Correlation between visual acuity, external limiting membrane and photoreceptor status in patients with neovascular age-related macular degeneration treated with bevacizumab

Korelacija između vidne oštrine, spoljašnje granične membrane i fotoreceptora kod bolesnika sa neovaskularnom senilnom degeneracijom žute mrlje lečenih bevacizumabom

Abstract

Background/Aim. The integrity of outer retinal structures, primarily the photoreceptor layer, is important because of its direct correlation with visual acuity. The aim of this study was to investigate the correlation between best-corrected visual acuity (BCVA), the foveal photoreceptor-inner segment/outer segment (IS/OS) junction and external limiting membrane (ELM) in patients with neovascular age-related macular degeneration (NVAMD) after the treatment with bevacizumab, as well as the correlation between the above-mentioned parameters and different types of neovascular membrane, classified by fluorescein angiography (FA).

Methods. The study included 82 patients with NVAMD, treated with intravitreal bevacizumab. All patients underwent a basic ophthalmological examination, FA and optical coherence tomography (OCT). Based on the results of FA, all the patients were divided into two main groups – type I (the occult and minimally classic) and type II (classic and predominantly classic) of the choroidal neovascular membrane (CNV). The OCT images revealed either the presence or the absence of IS/OS and ELM.

Results. After the treatment, the mean best corrected visual acuity improved significantly in both groups (p < 0.01). Preserved IS/OS and ELM were registered in a smaller number of patients as compared to the condition before the treatment (p < 0.01). After the treatment, the mean BCVA was significantly better in patients with preserved IS/OS and ELM (p < 0.01). In addition, we registered a higher number of patients with preserved ELM in the first group than in the second group (p < 0.01), whereas there was no significant difference in the integrity of IS/OS between the groups (p > 0.05).

Conclusion. The patients with preserved IS/OS and ELM achieved better final visual acuity as compared to the patients without preserved IS/OS and ELM. In our patients, the absence of IS/OS and ELM were more frequent in type II (classic and predominantly classic) CNV than in type I (the occult and minimally classic) CNV.

Key words: retina; macular degeneration; neovascularization, pathologic; bevacizumab; tomography, optical coherence; fluorescein angiography.

Apstrakt

Uvod/Cilj. Integritet spoljašnjih struktura mrežnjače, primarno sloja fotoreceptora, važan je zbog njihove direktnje povezanosti sa oštrinom vida. Cilj rada bio je da se ispita povezanost između najbolje korigovane vidne oštrine, fovealnih fotoreceptora i spoljašnje granične membrane kod bolesnika sa neovaskularnom senilnom degeneracijom žute mrlje nakon lečenja bevacizumabom, kao i odnos navedenih parametara sa različitim tipovima neovaskularne membrane klasifikovane metodom fluoresceinskog angiografije. Metode. Istraživanjem su obuhvaćena 82 bolesnika sa neovaskularn…

 Introduction

Choroidal neovascular membrane (CNV) is the main cause of severe visual impairment in patients with wet age-related macular degeneration (AMD). Vascular endothelial growth factor (VEGF) is one of the main factors responsible for the development of AMD. The drugs that block its activity, anti-VEGF drugs, have improved considerably the course of this disease and the patients’ quality of life 1–3. Today, they represent standard therapy for the treatment of neovascular AMD (NVAMD) 4, 5.

Bevacizumab (trade name Avastin®) is a monoclonal VEGF antibody, approved for intravenous use in the management of colorectal carcinoma. In ophthalmology, it is used off-label. The first papers related to the intravitreal administration of this drug in the treatment of NVAMD were published as early as in 2006–2008.

Optical coherence tomography (OCT) is a useful tool in the diagnosis and monitoring of AMD. After the introduction of a spectral-domain OCT (SD-OCT), which provides image resolution of up to 5 µm, it becomes possible to see clearly all retinal structures 9, 10. The monitoring of CNV [presence of intraretinal fluid, subretinal fluid or fluid under the retinal pigment epithelium (RPE)] is important for the assessment of its activity. After the treatment, i.e. after the fluid has retrograded, a subretinal fibrosis or atrophy can occur, which consequently influences the status of inner segment/outer segment (IS/OS) and external limiting membrane 11.

The monitoring of the integrity of external retinal layers, primarily the photoreceptor layer, is important because of its direct correlation with visual acuity 12–15. In some studies, the IS/OS line on the SD-OCT images was reportedly a good indicator for predicting best-corrected visual acuity (BCVA) in NVAMD patients treated with anti-VEGF therapy 16. ELM status is another useful parameter during the evaluation of retinal morphology and function in patients with NVAMD 17.

The aim of this study was to investigate the correlation between BCVA, IS/OS and ELM in patients with NVAMD after the treatment with bevacizumab, as well as the correlation between the above-mentioned parameters and different types of neovascular membrane, classified by fluorescein angiography (FA).

Methods

This clinical, cohort, prospective, non-randomized study was conducted at the Military Medical Academy, Belgrade, Serbia between February 2013 and February 2015. The protocol of this study was approved by the Ethical Committee of the Military Medical Academy. The patients were informed about the off-label use of bevacizumab.

The study involved 105 patients in total. Out of that number, 23 patients were excluded due to insufficient documentation. Here we present 82 patients, in whom the fluid retreated after the sixth dose of the medication, i.e. the CNV activity decreased. CNV was considered active if contrast leakage was seen on FA and if OCT detected an increased and/or persistent presence of macular fluid. As there is no precise dosing protocol for this medication, based on our experience and after consulting literature, we opted for six-monthly doses.

All patients were over the age of 65 and were suffering from AMD-related subfoveal CNV which had not been treated previously. To qualify for the study, the patients had to have the mean BCVA of 0.05 or higher (Snellen chart). The patients did not have acute or chronic eye inflammations, other fundus changes or decompensated glaucoma. The presence of early-stage/cataract or pseudophakia were not a reason for the exclusion from the study.

At the beginning, each patient underwent the following: complete ophthalmological examination, BCVA assessment, FA on Topcon Trc-NW7SF fundus camera and OCT on Topcon 1000-SD OCTTOp 1000-T3D3. Based on the FA results, the patients were divided into two main groups, depending on whether they had Type I CNV (the occult and minimally classic) or Type II CNV (classic and predominantly classic) membrane. Each group consisted of...
41 patients. Using OCT scans we detected the presence or the absence of ELM and IS/OS. This analysis was conducted by two ophthalmologists independently and in the case of inconsistencies in the findings, it was supervised by the mentor. Structural changes of CNV seen on OCT were analyzed in the subfoveal area of 1 mm. The OCT findings were analyzed immediately before the administration of each dose of the medication. In cases where macular fluid disappeared completely before the sixth dose of the medication was given, we interrupted the treatment and such patients were excluded from the study.

All the patients received 1.25 mg of bevacizumab (0.05 mL of the commercial phial of Avastin®) intravitreally. The control assessments were carried out on the first, seventh and thirtieth days following the intervention. One month after administration of the first dose, the next dose was administered. A total of six doses were administered in one-month intervals (+2).

Statistical analysis was performed before and after the therapy, using SPSS version 19.0 (SPSS., Chicago, IL, USA). Distribution of variables was assessed by Kolmogorov-Smirnov test and it was concluded that BCVA-related data should be analyzed using non-parametric statistics. The values within a group were analyzed by Friedman’s test. For the comparison of BCVAs between the groups, we used the Mann-Whitney U-test.

Results

The patients [82 patients (eyes), 41 in each group] were between 65 and 92 years old. The average age was 77.2 years in the first group and 77.8 years in the second, one. The mean initial BCVA was 0.19 in the first group, and 0.14 in the second one. After the therapy, the mean BCVA was 0.42 in the first, and 0.30 in the second group ($p < 0.01$) (Table 1).

Before the therapy, preserved ELM was registered in all patients (100%), in both groups. In the first group, after the sixth dose, ELM was preserved in 26 patients (63.4%) and in the second one in 11 (26.8%) patients. Before the treatment, the IS/OS was preserved in 39 (95.2%) patients from the first group, and in 35 (85.4%) patients in the second group. After the treatment, the number of patients with preserved IS/OS in the first group decreased to 28 (68.3%) and to 22 (53.4%) in the second group (Tables 2).

In the first group, in patients whom ELM was preserved, the mean BCVA was 0.19. After the treatment, ELM was preserved in 26 patients and their mean BCVA was 0.53 ($p < 0.01$). After the treatment, in 15 patients in whom ELM was not preserved, the mean BCVA was 0.23 (0.19–0.23) ($p < 0.05$). In the first group, IS/OS were preserved in 39 patients before the treatment, and their mean BCVA was 0.15. After the treatment, IS/OS was preserved in 28 patients, with mean BCVA of 0.39 ($p < 0.01$). In two patients without preserved IS/OS before the therapy the mean BCVA was 0.10, and after the therapy, IS/OS were absent in 13 patients with mean BCVA 0.18 ($p > 0.05$) (Table 3).

In the second group, in patients whom ELM was preserved, the mean BCVA was 0.14. After the treatment, ELM was preserved in 11 patients and their mean BCVA was 0.46 ($p < 0.01$). In 30 patients in whom ELM was not preserved, after the treatment the mean BCVA was 0.24 ($p < 0.05$). In the second group, 35 patients had complete IS/OS before the treatment, and their mean BCVA was 0.22. After the treatment, IS/OS were preserved in 22 patients, with mean BCVA of 0.33 ($p < 0.05$). In six patients without preserved IS/OS before the therapy the mean BCVA was 0.15, and after the therapy IS/OS were absent in 19 patients with mean BCVA 0.22 ($p < 0.05$) (Table 3).

Group I – occult and minimally classic membrane;
Group II – classic and predominantly classic membrane.

The results of our study showed that after the treatment there were 26 patients with preserved ELM in the first group (the occult and minimally classic CNV), as compared to 11 patients in the second group (classic and predominantly classic) \((p < 0.01)\). After the treatment, IS/OS were preserved in 28 patients in the first group and in 22 patients in the second group \((p > 0.05)\) (Table 1).

Discussion

The results of our study confirmed that the visual acuity in patients with wet AMD was significantly improved after the intravitreal administration of bevacizumab, as previous studies had demonstrated \(^1,3,6–8\).

There are several types of anti-VEGF medications, registered for intravitreal administration. Since the study by Martin al. \(^3\) CATT showed that ranibizumab is not superior to bevacizumab in terms of their effects, and, as bevacizumab is significantly cheaper, we decided to use bevacizumab.

The protocol for the administration of anti-VEGF drugs has not been precisely established yet. In the studies such as ones by Brown et al. \(^1\) (ANCHOR) and Rosenfeld et al. \(^2\) (Marina), this medication was administered monthly. Some studies dealt with treat-and-extend dosing regimens, whereas in other studies, the dosing regimen was pro re nata (PRN) – treat and observe \(^5\). Based on our previous experience, we decided to apply a monthly dosing regimen.

The correlation between the type of neovascular membrane (identified by FA), and its structural characteristics (identified by OCT) was described by Freund et al. \(^18\). The final visual acuity in patients with NVAMD is influenced by various changes in the macula (subretinal, intraretinal or fluid under the RPE) \(^11,19\). The drug itself has no effect either on ELM or on IS/OS, but after the treatment is over, and after the fluid retreats, the integrity of these parameters influences the final visual acuity, which was described by many authors \(^14,15,20\).

A correlation between visual acuity, ELM and IS/OS integrity in the treatment of neovascular AMD with photodynamic therapy was described as early as in 2010 by Oishi et al. \(^15\), and was also mentioned by Sayanagi et al. \(^16\), but subsequent to anti-VEGF therapy. The importance of these structures in the preservation of vision in patients with uveitic macular oedema was described by Tortorela et al. \(^14\).

Sayanagi et al. \(^16\) confirm the importance of IS/OS status in patients who were given anti-VEGF therapy and conclude that IS/OS is a good indicator in terms of prognosis for visual acuity following an anti-VEGF therapy.

Shin et al. \(^20\) conclude that the integrity of foveal photoreceptors is strongly correlated with final visual acuity after the treatment in patients with NVAMD.

Kwon et al. \(^13\) conclude that IS/OS and ELM can be good predictors of visual acuity after anti-VEGF therapy.

Upon the analysis of our data, we noted that the presence of ELM and IS/OS correlate with better visual acuity, both before and after the therapy. A significant role of ELM and IS/OS, as important prognostic factors for final BCVA, was also confirmed by Mathew et al. \(^19\).

Our study showed the significant improvement of BCVA in patients with preserved ELM and IS/OS in both groups, whereas in patients with not preserved ELM and IS/OS, the BCVA was lower (there was an improvement, but the difference was not statistically significant).

The number of patients with preserved IS/OS and ELM decreased after the treatment, especially in the second group, where the number of patients with preserved ELM after the therapy was considerably lower. This means that there were more patients with preserved ELM and IS/OS in the first group (the occult and minimally classic CNV) than in the second group (classic and predominantly classic CNV). The literature offers diverse findings regarding this issue. Bloch et al. \(^21\) in their study obtained the findings similar to ours, while Freund et al. \(^18\) in their study actually argue that the response to anti-VEGF therapy is better in patients from the second group (classic and predominantly classic CNV).

The studies, such as ANCHOR \(^1\) and MARINA \(^2\), showed that, regardless of the type of neovascular membra-
ne, classified by FA method, the vision would improve after the anti-VEGF therapy. We confirmed such findings, as well as that visual acuity is considerably better if IS/OS and ELM are preserved at the end of the treatment.

Conclusion

The presence of ELM and IS/OS is an important prognostic factor for final visual acuity in patients with NVAMD. The absence of ELM and IS/OS is more frequent in type II CNV (classic and predominantly classic) than in type I CNV (the occult and minimally classic) and this is the reason why these patients can be expected to have somewhat lower final visual acuity after the anti-VEGF therapy.

The development of modern technology provides an even more precise insight into the structure of the neovascular membrane, so future analyses will be able to define even more precisely its various structural parameters and open new approaches to treating these patients.

Calculation of electromagnetic field from mobile phone induced in the pituitary gland of children head model

Izračunavanje elektromagnetnog polja mobilnog telefona unutar hipofize na modelu glave deteta

Abstract

Background/Aim. A mobile phone is a source of electromagnetic radiation located close to the head and consequently its intense use may cause harmful effects particularly in younger population. The aim of this study was to investigate the influence of electromagnetic field of the mobile phone on the pituitary gland of the child. Methods. In order to obtain the more accurate results for this research 3D realistic model of child's head whose size corresponds to an average child (7 years old) was created. Electric field distribution in child head model and values of Specific Absorption Rate (SAR) at the region of pituitary gland were determined. This study was performed for the frequencies of 900 MHz, 1,800 MHz, and 2,100 MHz, as the most commonly used in mobile communications. The special attention was dedicated to the values of the electric field and the values of the SAR in the pituitary gland. For all frequencies over 10 g and 1 g of tissue average SAR was calculated. The electric field distribution and values of average SAR for 10 g and 1 g through the model of child's head were obtained by the using numerical calculation based on the Finite Integration Technique (FIT). Results. The largest value of electric field in the region of the pituitary gland was at the frequency of 900 MHz, as a consequence of the highest penetration depth. Lower values of the electric field in the region of the pituitary gland were at frequencies of 1,800 MHz and 2,100 MHz. The SAR in the pituitary gland decreased as the frequency increased as a direct consequence of lower penetration depth. Conclusion. The electric field strength from a mobile phone is higher than the value specified by standards for the maximum allowable exposure limits. The high values of the electric field are not only in the vicinity of a mobile phone but also in tissues and organs of the human head. Particular attention should be paid to the exposure of children to radiation of mobile phones. Smaller dimensions of children’s head and smaller thickness of tissues and organs have as a consequence greater penetration of electromagnetic waves.

Key words: cellular phone; electromagnetic fields; child; models, theoretical; pituitary hormones.

Introduction

The wide variety of available options of mobile phones such as games, the internet, calls and video calls, as well as their accessible prices, have led to the daily use of mobile phones mostly in the younger population (children) which can be measured in hours. The mobile phone is a source of electromagnetic radiation which is located close to the head and because of that, the intense use of mobile phones in the younger population causes concern for health effects.

The influence of electromagnetic field from a source of electromagnetic radiation such as mobile phone close to child’s head is bigger than an influence on the adult head. This is due to smaller dimension of child's head and consequently thinner pinae and skulls. Because of that in the case of child’s head, the source of electromagnetic radiation is closer to the brain and pituitary gland than in the case of adults head. Relevant data show that the exposure of children to electromagnetic radiation is higher than adult exposure 1,2.

Because of ethical considerations, human exposure to electromagnetic fields in experimental purposes is limited. Due to this, it is much more convenient to develop a realistic model of the human head by using numerical simulation 3. Numerical analyses of the human head exposed to electromagnetic radiation of mobile phones provide useful information about absorbed electromagnetic energy under different conditions of exposure. The International Agency for Research on Cancer (IARC) has classified the radiation of electromagnetic fields in 2B group as possibly carcinogenic to human, based on an increased risk of a malignant type of brain cancer. In this category, there is a limited evidence of carcinogenicity in humans and less than sufficient evidence of carcinogenicity in experimental animals 4.

The most important indicator when considering the health risk as a result of the effect of electromagnetic fields is the Specific Absorption Rate (SAR). SAR is directly dependent on the electromagnetic properties of biological tissues exposed to the effects of electromagnetic waves and can be defined as (Equation 1):

$$\text{SAR} = \frac{\sigma |E|^2}{\rho}$$

where $E$ is the maximum value of the internal electric field, $\sigma$ is the conductivity of the tissue and $\rho$ is the density of the tissue. Maximum values of SAR which must not exceed, are defined in Regulation of the limits of exposure to non-ionizing radiation, Official Gazette of the Republic of Serbia, no. 36/09. This regulation defines the limits of exposure to non-ionizing radiation, or the basic restrictions and reference boundary levels of the population exposure to electric, magnetic and electromagnetic fields of different frequencies 5.

In this research, the level of electric field strength due to mobile phone and SAR values at the region of pituitary gland were determined.

The pituitary is a small gland which has a diameter of around 1cm and a weight of about 0.5–1 g, and it is located at the base of the brain. Physiologically it can be divided into two parts: the front part called the adenohypophysis and the rear part called neurohypophysis. Adenohypophysis secretes six very important hormones, which have a very significant role in the control of metabolic functions of the whole organism such as prolactin, growth hormone (GH), adrenocorticotropin hormone (ACTH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH). The main role of rear part or neurohypophys is to store antidiuretic hormone (ADH) and oxytocin. Hormones from the hypothalamus almost completely regulate the secretion of pituitary hormones which are delivered through the bloodstream to the pituitary gland.

As shown in one study 6, exposure to 900 MHz of global system for mobile communication radio frequency (GSM RF) on pituitary hormone levels in healthy males such as: TSH, GH, prolactin and ACTA, led to significant decreases of concentrations of GH and cortisol for about 28% and 12%, respectively.

Due to a higher level of electromagnetic radiation within the child’s head compared to that found inside adult’s head, the electric field can be one of the causes of serious biological effects on the pituitary gland. Because of harmful effect previously mentioned on the pituitary gland and consequently on the concentration of GH which is essential for normal growth of the child, in this paper special attention is devoted to numerical calculation and distribution of electrical field and SAR in the region of this gland for 7-years old child. Also in this study, an overview of the possible biological effects that may occur in pituitary gland due to exposure to electromagnetic fields is presented.

Methods

In order to obtain more accurate results for this research 3D realistic model of child's head whose size corresponds to an average child (7 years old) had to be created 7,8. This model of child’s head consisted of following tissues and organs: skin, fat, muscle, skull, jaw with teeth, tongue, eyes, vertebrae, cartilage, spinal cord, cerebrospinal fluid, brain, and pituitary gland.

All of these tissues and organs had to be described by adequate electromagnetic parameters such as electric conductivity, permittivity, heat capacity, density and thermal conductivity 9. These electromagnetic characteristics vary with frequency and their values for frequencies of 900 MHz, 1,800 MHz, and 2,100 MHz, as the most often used in mobile communication, are shown in Table 1.

Modeling of 3D child’s head model was performed in two stages. First external look for every tissues and organs was created in 3D Max Studio 10. The second step was creating a full model with actual tissues and organs and connecting certain electromagnetic properties with corresponding tissues and organs by using software package CST Microwave Studio 11. The same software was used for simulation of the electromagnetic field and its influence on child’s head. Numerical calculation method used in this software was based on the Finite Integration Technique 12.

External look, horizontal and vertical cross-sections of actual tissues and organs are shown in Figures 1 and 2 with organs numbered according to their numbers in Table 1.

### Table 1

Average values of electromagnetic properties of tissues and organs at frequencies of 900 MHz, 1,800 MHz and 2,000 MHz

![Fig. 1 – External look of the child’s head model.](image)
In this study actual smartphone (Figure 1) was used as a source of electromagnetic radiation. The mobile phone consisted of following parts: planar inverted F antenna (PIFA), display and mobile housing. The planar inverted F antenna (PIFA) as a source of electromagnetic radiation was modeled for three different frequencies: 900 MHz, 1,800 MHz, and 2,100 MHz, with reference power of $P = 1W$ and impedance of $Z = 50 \Omega$.

The numerical calculation was performed for open space (reflected electromagnetic waves and the other sources of electromagnetic radiation were not taken into consideration). The only source of electromagnetic radiation in this simulation was a mobile phone with an output power of 1W, defined according to the Standard of the Institute of Electrical and Electronics Engineers (IEEE) C.95.3.

### Results

The penetration depth of the electric field was the largest in the case of the electric field at a frequency of 900 MHz (Figure 3a). On the other hand, the penetration depth of the electric field at the higher frequencies was smaller resulting in a stronger electric field in tissues that are close to the source of electromagnetic radiation such as mobile phone (Figures 3b and 3c). The peak of the electric field in the pituitary gland at the frequency of 2,100 MHz was less than those at the frequencies of 1,800 MHz and 900 MHz (0.3045 V/m, 0.8643 V/m, and 5.6615 V/m, respectively) (Figure 4).

SAR values averaged over 1 g and 10 g of the tissue for all three frequencies used in this study are presented in Figures 5 and 6, respectively.

Because the penetration depth of electric field was the largest in case of the frequency of 900 MHz (Figure 6), SAR values in the region of the pituitary gland was the highest for this frequency and amounted $SAR_{1g} = 0.08521 \, W/kg$ (Figure 5) and $SAR_{10g} = 0.10325 \, W/kg$ (Figure 6).

### Discussion

In this study, the electric field distribution within the child’s head model was investigated for different frequencies

of a mobile phone. Our results showed that the penetration depth of the electric field was the largest at a frequency of 900 MHz and decreased at higher frequencies resulting in a stronger electric field in tissue that was close to the source of electromagnetic radiation like a mobile phone. The wavelength of electromagnetic waves has an impact on penetration depth because it varies for different frequencies and it has to be taken into consideration that electromagnetic properties are different for different biological tissues.

Generally, the one part of the energy due to the propagation of electromagnetic waves penetrates into certain biological object and it is being absorbed. Differences of wave energy at the boundaries of a biological object (the input energy and output energy) represent the absorbed energy. Because of the need to precisely introduce this absorbed energy it was defined as the term Specific Absorption Rate - SAR. The values of the SAR are different for different tissues and electromagnetic waves of different characteristics, in this case, different frequencies. It can be said that SAR characterizes the interaction of electromagnetic fields with biological tissue. SAR is related to a certain point as an extremely small area in a biological tissue in which the electromagnetic field can be considered as homogeneous one. More practical value is the average SAR as the ratio of the absorbed power in the body and the body mass of biological entity.

For this research, values for the average SAR over 10 g and 1 g of tissue were calculated. Because of different frequencies values of SAR varied. Accordingly, the penetration depth of the electric field was the largest in case of a frequency of 900 MHz, and SAR values in the region of the pituitary gland were the highest for this frequency.

The results obtained in this paper are compared with those obtained in the study of Krstić et al. After comparison, it can be concluded that the value of SAR in the region of pituitary gland for child’s head model used in this research, is greater than SAR in a model of adult person’s head with few layers in that study. SAR in a case of child’s head model is almost five times greater than results in a case of adult’s head model. This is expected due to different characteristics of the model: size, different thickness of layers and therefore the pituitary gland was at greater distances from the source in case of adult person’s head model.

There are many differences among different countries in Europe in terms of upper limits for RF radiation from GSM mobile telephony. Based on Recommendation 1999/519/EC, the limit values which are prescribed for the electric field strength for the following frequencies: 900 MHz, 1,800 MHz, and 2,100 MHz, are 41 V/m, 58 V/m i 61 V/m, respectively. The certain European governments have adopted lower values such as for example Greece (32 V/m, 45 V/m and 47 V/m), Belgium (21 V/m, 29 V/m and 31 V/m), Serbia (16.5 V/m, 23.3 V/m and 24.4 V/m), Slovenia (13 V/m, 18 V/m and 19 V/m), Poland (7 V/m, 7 V/m and 7 V/m), Italy (6 V/m, 6 V/m and 6 V/m), Switzerland (4 V/m, 6 V/m and 6 V/m), etc. for all three frequencies, respectively.

The values for the maximum field strength that are prescribed by the standard are given for free space in the absence of people. We have to keep in mind that the values for field strength inside the biological tissues or organs are lower because of the propagation through the material environment and due to the increasing distance from the radiation source.

If the value of the field is known inside biological tissue then, based on the boundary conditions at the surface of the two separate areas, the value of the incident field can be evaluated. Since the value of the electric field in the pituitary gland is known, based on the relationship that is valid for the normal vector components of the electric field at the separate area, the value of the field before the penetration of EM waves in the pituitary gland can be determined.

Based on the value of the dielectric constant and conductivity of air and pituitary gland for different frequencies, the ratio of electric fields strengths at the separate surface of these two areas can be approximately determined. This is certainly the worst case, from the standpoint of the electric field strength, because in this case it does not take into consideration the impact of other layers on the weakening of electromagnetic wave that spreads from the radiation source. However, this approach can give us information about the minimum field strength to which man is exposed, and if it is greater than allowed.

The normal vector components of electric field at the crossover semiconductor environment is determined from the expression

\[
\frac{E_1}{E_2} = \frac{\sigma_1 + j\omega \varepsilon_1}{\sigma_2 + j\omega \varepsilon_2}
\]

For different frequencies and the corresponding values for the dielectric constant and conductivity of the air and the pituitary gland, the ratio of normal components of the electric field for these two environments is calculated by using previously formula (2) and results are:

\[
\left| \frac{E_{\text{air}}}{E_{\text{p. gland}}} \right|_{f=0.9\text{GHz}} \approx 63 \, \text{V/m},
\]

\[
\left| \frac{E_{\text{air}}}{E_{\text{p. gland}}} \right|_{f=1.8\text{GHz}} \approx 60 \, \text{V/m}, \text{and}
\]

\[
\left| \frac{E_{\text{air}}}{E_{\text{p. gland}}} \right|_{f=2.1\text{GHz}} \approx 59.5 \, \text{V/m}.
\]

Based on the previously obtained values for the electric field strength in the pituitary gland, the values of the electric field strength in the air are:

\[
E_{\text{air}} \bigg|_{f=0.9\text{GHz}} \approx 356.67 \, \text{V/m},
\]

\[
E_{\text{air}} \bigg|_{f=1.8\text{GHz}} \approx 51.86 \, \text{V/m}, \text{and}
\]

\[
E_{\text{air}} \bigg|_{f=2.1\text{GHz}} \approx 18.12 \, \text{V/m}.
\]

If we compare this value with the maximum permissible values specified in the above mentioned countries, we can conclude that they are considerably higher or in range with the maximum allowable ones. Of course, if we take into account the impact of all other layers between the radiation source and pituitary gland obtained values would have been far greater.

Pituitary gland as one of the most important glands of the endocrine system, via ACTH has an impact on the cortex.
of the adrenal gland. In this way, it stimulates the secretion of steroid hormones.

Some investigations revealed that stimulation of the adrenal axis by electromagnetic radiation from a mobile phone in rats has as a consequence general hyperthermia. In animals exposed to high levels of electric fields, stimulation of the hypothalamic-hypophysial-adrenocortical (HHAX) axis was found, mediated by the central nervous system (CNS)18.

Another very important function of the pituitary gland is that it secretes gonadotropins FSH and LH that regulate testicular spermatogenesis and steroidogenesis. The impact of a mobile phone radiation on gonadotropins level has been considered in man and animals. The results of some studies have shown that a mobile phone radiation cannot cause significant biological effects. But there is a possibility that the time of exposure to radiation from a mobile phone in these studies was not long enough to show some significant biological effects19–20.

Research conducted by Fang et al.19 showed progressive histological derangement in rat pituitary glands. These derangements were manifested in the form of swollen mitochondria as well as dilatation of Golgi complex and diffusive lysosomes. Also, this research revealed that with increasing duration of exposure and electromagnetic wave energy this disorder increased. For instance, it has been observed also mitochondrial vacuolization, the formation of myelin figures, distinct dilatation of endoplasmic reticulum, the occurrence of numerous secondary lysosomes, and clustering of heterochromatin under the nuclear membranes19.

In the study of Eskander et al.21, it was shown that people living a long period of time in the vicinity of base stations have a significant reduction of the release into the blood of a number of hormones, including ACTH which is produced and secreted by the anterior pituitary gland21. The highly significant decrease of serum cortisol levels in people exposed to electromagnetic radiation was also found.

Conclusion

The penetration depth of the electric field is the largest at the frequencies of 900 MHz and decreases, at the higher frequencies, resulting in a stronger electric field in the tissues that are close to the source of electromagnetic radiation (mobile phone).

Results obtained by numerical analysis show that the electric field at the frequency of 900 MHz has the greatest impact on the pituitary gland, which is a consequence of the highest penetration depth as mentioned before.

This level of radiation may cause substantial harmful health effect in children having in mind our study results that the level of electric field strength inside pituitary gland is higher than the values for the maximum field strength specified by the standard.
